## Abstract

A deep underwater Cherenkov telescope has been operating since 1993 in stages of growing size at 1.1 km depth in Lake Baikal. The key component of the telescope is the Optical Module (OM) which houses the highly sensitive phototube *QUASAR-370*. We describe design and parameters of the *QUASAR-370*, the layout of the optical module, the front-end electronics and the calibration procedures, and present selected results from the five-year operation underwater. Also, future developments with respect to a telescope consisting from several thousand OMs are discussed.

## 1 Introduction

The Baikal Neutrino Telescope is being deployed in the Siberian Lake Baikal, about 3.6 km from shore at a depth of 1.1 km [1], [2]. The central mission of the project is the detection of extraterrestrial sources of high energy neutrinos. Other fields of interest [3] are the search for neutrinos from WIMP annihilation in the Earth or the Sun, for neutrino oscillations, and for slowly moving bright objects like GUT monopoles. Standard cosmic ray physics with muons generated in the atmosphere is covered as well as limnological and ecological questions.

In deep underwater detectors, clear water serves as target material for neutrino interactions, as Cherenkov radiator for charged particles, and as a shield against atmospheric muons and sunlight. Energetic neutrinos are detected easiest by mapping the Cherenkov light from muons produced in charged current interactions. "Mapping" means measurement of the photon arrival times at photodetectors distributed over a large volume. The feebleness of the light signal requires a large-area, large-acceptance light detector with single photoelectron resolution. Mapping of the Cherenkov cone with a spatial accuracy not worse than the OM diameter requires a time resolution of a few nanoseconds. The water depth demands pressure protection of the sensor.

The present paper describes design and operation of the components of the optical module (OM) most of which have been developed within our collaboration. After a short presentation of the telescope in section 2, section 3 covers the design and the parameters of the phototube *QUASAR-370*. Section 4 gives the construction of the OM, section 5 describes the electronics and discusses the operational principle of two PMTs switched in coincidence. Section 6 presents results from the different methods of OM calibration, whereas in section 7 the long-term operation underwater is evaluated and some selected results of the telescope operation are given. Section 8 summarizes the results and sketches routes of further development.

## 2 The Telescope *NT-200*

After numerous experiments with prototype configurations [2], in April 1993 we deployed a first underwater detector allowing three-dimensional track reconstruction of muons. This array *NT-36* consisted of 36 OMs at 3 strings [4]. It was replaced in 1994 by a slightly modified version, in 1995 by a 72-OM array, in 1996 by *NT-96* consisting of 96 OMs at 4 strings, and in 1997 by a 144-OM array. These detectors have been steps towards the Neutrino Telescope *NT-200* [1,2] with a total of 192 OMs. *NT-200* was completed in April

1998 and is presently taking data. It is sketched in Fig. 1.

The OMs consist of a pressure glass housing equipped with the *QUASAR-370*. They are grouped in pairs along the strings. The two PMTs of a pair are switched in coincidence, defining a *channel*. The "constructional" basic building block (called "*svjaska*") consists of two pairs of OMs, and the *svjaska* electronics module, *SEM*, which houses control units, power supply and the front-end electronics.

Fig. 1. Schematic view of the Baikal Telescope *NT-200*. The expansion lefthand shows 2 pairs of OMs ("*svjaska*"), with the *svjaska* electronics module housing parts of the control and read-out electronics.

A *muon trigger* is formed if  $\geq m$  channels are hit within a time window of 500 nsec (this is about twice the time a relativistic particle needs to cross the *NT-200* array). The value  $m$  is typically set to 3 or 4. Times and amplitudes are digitized in the string electronic modules.

A second system "*monopole trigger*" searches for counting rate patterns characteristic for slowly moving bright particles like nuclearities or GUT magnetic monopoles catalyzing proton decays. Depending on the velocity of the object,

such events could cause enhanced counting rates in individual channels during time intervals of 0.1 - 0.8 msec, separable from Poissonian noise.

### 3 The Phototube

#### 3.1 Construction and operational principle

The *QUASAR-370* consists of an electro-optical preamplifier followed by a conventional photomultiplier (PMT) - see Fig. 2. In this hybrid scheme, photoelectrons from a large hemispherical cathode with  $> 2\pi$  viewing angle are accelerated by 25 kV to a fast, high gain scintillator which is placed near the center of the glass bulb. The light from the scintillator is read out by a small conventional PMT named *UGON*. One photoelectron emerging from the hemispherical photocathode yields typically 25 photoelectrons in the conventional PMT. This high multiplication factor of the electro-optical preamplifier results in an excellent single electron resolution – important for the detection of low level light pulses and background suppression. Due to the fast acceleration of primary photoelectrons by 25 kV high voltage, the time jitter can be kept low. This is most important for accurate track reconstruction. Last not least, the tube is almost insensitive to the Earth's magnetic field.

Fig. 2. Cross section of the QUASAR-370 tube

A hybrid phototube of this kind, XP2600, was first developed by PHILIPS [5,6]. After first experience with the XP2600 we followed their basic design and developed the "QUASAR".

First versions of the *QUASAR*-tube had a spherical shape, with diameters of 30 cm (*QUASAR-300*) and 35 cm (*QUASAR-350*), respectively. The latest version – *QUASAR-370* – has a nonspherical (mushroom) shape of the glass bulb to provide more isochronic photoelectron trajectories. Fig. 3 gives the measured relative transit time as a function of the zenith angle. The transit time differences are minimized to  $\leq 2.0$  nsec.

Fig. 3. Measured cathode transit time difference for *QUASAR-370* (N° 254) versus zenith angle  $\theta$ , for two azimuth angles  $\Phi$ .

Fig. 4. Relative sensitivity of *QUASAR-370* (N° 254) vs. zenith angle  $\theta$ , for two azimuth angles  $\Phi$ .

The spherical "face" region of the bulb has a diameter of 37 cm. Modifications towards the mushroom form are made at large zenith angles. The bulb is manufactured from borosilicate glass S49-1 by the EKRAN company, Novosibirsk. The photocathode is of the bialkali type ( $K_2CsSb$ ). Its spectral response is typical for this type of photocathode, with a maximum at  $\lambda = 400-420$  nm. The spectral sensitivity exceeds 60 mA/W at  $\lambda = 420$  nm which corresponds to  $\sim 20\%$  quantum efficiency. The non-uniformity of the response across the photocathode is less than 30% (see Fig. 4).

The luminescent screen is made from pulverized phosphor,  $Y_2SiO_5$  (YSO). This scintillator has a light yield of 20 - 30% relative to NaI(Tl) and 30 - 40 ns decay time.

### 3.2 Single Photoelectron Resolution

The single photoelectron resolution of the *QUASAR-370* is defined mainly by the gain  $G$  of the electro-optical preamplifier:

$$G = \frac{\text{number of photoelectrons detected by small PMT}}{\text{number of photoelectrons at the preamplifier photocathode}}. \quad (1)$$

Figs. 5 and 6 show typical charge distributions for single- and multi-photoelectron pulses of a *QUASAR-370*. The high amplification factor  $G$  allows to separate pulses of one and two photoelectrons and to identify even the shoulder from 3 p.e. events. The light pulse has been generated by a light emitting diode. The distribution labeled "single p.e." has been obtained by attenuating the LED to a level when only every tenth LED pulse triggered the *QUASAR*.

Averaged over 100 tubes, the mean values for single photoelectron resolution  $SPR$ , peak-to-valley ratio  $P/V$ , and gain  $G$  are

- $SPR \approx 70\%$  (FWHM),
- $P/V \approx 2.5$ ,
- $G \approx 25$ .

Fig. 5. Charge distribution for single p.e. events.

Fig. 6. Charge distribution for multi p.e. events.

### 3.3 Time Response

A single photoelectron pulse of the *QUASAR-370* is a superposition of  $G$  single photoelectron pulses of the small tube *UGON*, distributed exponentially in

time:

$$P(t) = \frac{1}{\tau} \exp\left(-\frac{t}{\tau}\right), \quad (2)$$

with  $\tau$  being the time constant of the scintillator. Figs. 7 and 8 show the corresponding typical pulseforms of single and multi-photoelectron pulses.

Fig. 7. Typical pulse form of a single p.e. pulse (10 mV/div vertically and 25 nsec/div horizontally).

Fig. 8. Typical pulse form of a multi-p.e. pulse (100 mV/div vertically and 25 nsec/div horizontally).

The best single photoelectron time resolution is obtained by using a double threshold discriminator as sketched in Fig. 9. It consists of two discriminators with different thresholds and integration constants: a *timing* discriminator with a threshold of  $0.25 q_1$  and a *strobe* discriminator with a threshold of  $0.3 Q_1$  ( $q_1$  and  $Q_1$  are the most probable charges of a single photoelectron pulse from the small PMT and from the big photocathode, respectively).

The time is defined by the front of the first of the  $G$  single photoelectron pulses of the small PMT. In this case, the transit time distribution for single photoelectron pulses with respect to the big photocathode is described by

$$W_1(t) = \frac{G}{\tau} \exp\left(-\frac{G}{\tau}t\right). \quad (3)$$

$W_1(t)$  is determined by the scintillator decay time constant  $\tau$  and by the gain  $G$  of the electro-optical preamplifier. For the best tubes and an accelerating voltage of 25 kV,  $G$  is about 50, and the FWHM of  $W_1(t)$  is 1.8 nsec for point illumination. For typical tubes the transit time FWHM is between 2 and 3.5 nsec. Fig. 10 shows the single photoelectron transit time distribution for head-on full-cathode illumination. The measured FWHM (3.8 nsec) is a

Fig. 9. Block diagram of the discriminator.  $D_1$  – timing discriminator with threshold  $0.25 q_1$ ,  $D_2$  – strobe discriminator with threshold  $0.3 Q_1$  (see text).

convolution of the jitter for point illumination and the transit time differences from different parts of the photocathode.

We should note here that some "late" events contribute to the tail of the  $W_1(t)$  distribution. These events are due to backscattering of photoelectrons in the luminescent screen. Elastically (or nearly elastically) scattered electrons may leave the screen without yielding a signal above the discriminator threshold. They are bent back by the electrical field in the electro-optical preamplifier and hit the screen a second time. Due to the high voltage (25 kV), the scale of delay times of late events in the *QUASAR-370* is considerably smaller than

Fig. 10. Single photoelectron transit time distribution for head-on, full-cathode illumination of the photocathode of *QUASAR-370* (N<sup>o</sup> 1). The FWHM is 3.8 nsec.

in conventional PMTs – about 10 nsec compared to 30-100 nsec.

The level of ordinary afterpulses in the *QUASAR-370* is substantially less ( $\leq 2\%$ ) than in conventional PMTs. The reasons are *a)* the complete vacuum separation between the electro-optical preamplifier and the small PMT, and *b)* the low sensitivity of the photocathode to backscattered X-ray photons of typically 10 keV (compared to some 100 eV in conventional PMTs).

Table I summarizes the main parameters of the *QUASAR-370* and of the small PMT *UGON*.

Table I

|                                             | QUASAR-370          | UGON                |

## 4 Design of the Optical Module

### 4.1 General Description

The OM basically consists of the *QUASAR-370* enclosed in a transparent, nearly spherical pressure housing, see Fig. 11. The optical contact between the photocathode region of the tube and the pressure sphere is made by liquid glyzerine sealed with a layer of polyurethane. Apart from the PMT, the OM contains two HV supplies (25 kV and 2 kV) for the hybrid PMT, a voltage

divider, two preamplifiers, a calibration LED and a vacuum probe. Each OM is electrically connected to the Svjaska Electronics Module (SEM, see figs.1 and 15) by four electrical lines. They pass the signal driving the LED from the SEM to the OM, and the PMT anode and dynode signal from the OM to the SEM. The fourth cable supplies the low voltages for the PMT HV-system and the preamplifier. A vacuum valve (not shown in Fig. 11) allows to evacuate the sphere to 0.7 atm (see section 4.2). The OM is fixed to the string by a steel frame locked via a shackle. Fig. 12 shows a photography of an OM pair.

Fig. 11. Schematical view of an Optical Module

## 4.2 Pressure Housing

### *Early approaches*

For the single string installations operated up to 1989 at Lake Baikal, cylindrical housings made from epoxy reinforced fiber glass have been used. These OMs housed two 15-cm tubes with flat window, facing upward and downward, respectively. The PMTs were covered with end caps made from plexiglas. Limits on the flux of GUT monopoles catalyzing baryon decay as well as a variety of limnologically relevant results have been obtained with single strings carrying these OMs [2]. With the advent of big hemispherical tubes this solution was discarded. In parallel to the tests of the early versions of the *QUASAR* [9], we considered a pressure resistant phototube and tested pilot samples of appropriate glass spheres with 37 cm diameter and 0.8-1 cm wall thickness [11]. However, in order to have more flexibility for future improvements of the phototube, we soon decided to use separate PMTs and pressure housings.

Fig. 12. A pair of Optical Modules of the Baikal telescope. The photocathodes point upward. Clearly seen are the four electrical feedthroughs and the vacuum valve lefthand.

### *Present design*

Traditional housings for large deep underwater instruments consist of two hemispheres whose equatorial surfaces are carefully ground to match each other. 15" spheres are produced by BENTHOS Inc, USA, and Jena-Glass, Germany (VITROVEX). In 1987, together with the EKTRAN company (Novosibirsk) we started the design of an own pressure housing. It consists from the same S49-1 borosilicate glass used for the bulb of the *QUASAR-370*. Its refractive index is 1.47 - 1.48. Since we developed the housings for our own purpose, we could optimize form and dimensions to fit the demands of the Baikal experiment. The originally spherical form was elongated by adding a cylindrical part of 2 cm to the equator of each hemisphere. This allowed *i)* to avoid space problems when mounting the tube with its high voltage module into the housing and *ii)* additionally to use the same housing for the underwater modules housing electronics crates. The elongated housing is superior to a sphere with bigger diameter since the layer of immersion material between tube bulb and pressure housing can be kept thinner. This as well as the small wall thickness (1.0 cm compared to 1.4 cm for BENTHOS and VITROVEX) results in a low light absorption. The 1.4 cm spheres withstand a water depth of 6.7 km, the wall thickness of the EKTRAN sphere is sufficient to work at all depths in Lake Baikal (max. 1632 m). The transmission at 500 nm is 87 % for the EKTRAN sphere, and 83 % for the other two spheres.

In order to simplify the construction of the metallic belt used to clamp the

OM to the string, the wall thickness at the equator was increased to 13 mm, forming a flange. The hermetization of the OM along the equator is achieved by evacuating it via a special valve to 0.5-0.7 atm and sealing it by homogenizing adhesive tape.

### 4.3 Optical Contact

The immersion material filling the gap between the bulb of the phototube and the pressure housing should have *a)* a good transparency, *b)* an index of refraction close to that of glass and *c)* high elasticity in order to protect the bulb from deformation of the pressure housing ( $\Delta D \approx 0.5$  mm at 140 atm).

Fig. 13. Transmission curves of the EKRAN spheres (S49-1), the VITROVEX spheres (Rasotherm), 1.1 cm glycerine and 1.2 cm SEMICOSIL jelly. All curves are normalized to their maximum transparency at high wavelength.

In the standard approach, optically transparent silicon jelleys are used [12–14]. We have developed an alternative, new method: The gap between tube and housing is filled with glycerine and sealed by casting a liquid polyurethane compound to the glycerine surface. The compound, being lighter than glycerine, polymerizes and forms a stable sleeve. The sleeve prevents the glycerine to leak into the back hemisphere of the OM which houses the HV supplies and other electronic components. It fixes the position of the tube and at the

same time does not prevent the minor displacements necessary to balance the pressure deformations of the housing. The advantages of this method are the following: *a)* the index of refraction of glyzerine practically coincides with that of glass ( $n = 1.47$ ), *b)* there is no "delamination" of the immersion material from the glass, a phenomenon easily appearing when working with jelley, *c)* the cost is low. The disadvantage is the risk that the polyurethane might leak in which case not only the optical contact is lost but also the glyzerine may corrode the electronics.

In parallel, we use the standard method which we tested first in 1992. The gap is filled with a two-component silicon jelley (SEMICOSIL, produced by WACKER, Germany) with an index of refraction  $n \approx 1.40$ . Eight OMs (VITROVEX spheres) with SEMICOSIL jelley were underwater for one year in 1992/93, without showing any degradation of optical or mechanical characteristics. Presently, we use VITROVEX spheres and SEMICOSIL jelley for about 10 % of all OMs.

The transparencies of pressure housings, glyzerine and jelley are shown in Fig. 13 as a function of wavelength.

#### 4.4 *Hermetic connectors*

The design of our connectors and penetrators started from the vacuum-proofed HF connector SRG-50-863 produced in Russia. The connector has an impedance of 50 Ohms and withstands working voltages up, to 500 V and temperature extremes from  $-50^{\circ}\text{C}$  to  $+155^{\circ}\text{C}$ . Following the experience we had gained formerly with connectors produced by SEACON (USA), we modified the SRG-50-863 for deep underwater applications. The new connector is hermetic up to a pressure of 200 atm. The outer screen is in electrical contact with water. In salt water this would result in strong electro-corrosion; in fresh water, however, it is of negligible relevance. The hermetic connectors and penetrators developed in cooperation with the AKIN laboratory, Moscow, can be operated at all depths of Lake Baikal, i.e. down to 1.7 km.

## 5 **Operational Principle**

### 5.1 *Electronics*

The electronics, the trigger formation and the data aquisition system of the *NT-200* Telescope have been sketched in [1]. Here, we describe in more de-

tail the front-end electronics which is closely connected to the operational principle of an OM pair. It is housed in the OMs itself as well as in the Svjaska Electronics Modules (see Fig. 1). Fig. 14 shows a block diagram of the components.

#### *a) Optical Module*

The OM houses two DC-DC HV supplies, one with a fixed output voltage (presently 25 kV) for the *QUASAR* optical preamplifier, the other for the small PMT *UGON*, with a voltage remotely controllable in steps of 10 V from 1.00 to 2.27 kV. Both supplies can be remotely switched off/on. The anode signal is fed to an amplifier (10x), the signal from the 11th dynode to an inverting amplifier (3x). The amplifiers are mounted to a printed board. The voltage divider for the *UGON* is integrated to the photomultiplier itself. For amplitude calibrations, a LED is mounted close to the *QUASAR* photocathode. Its light level can be changed from 1 to 1000 photoelectrons.

#### *b) Svjaska Electronics Module*

The anode signals from the two *QUASARs* are processed by the *local trigger board*. It consists of two 2-level discriminators  $D_1$  and  $D_2$  as described in section 3, one for each OM, and a coincidence circuit. The threshold of  $D_1$  is set to  $0.25 a_1$ , with  $a_1$  being the mean pulse height of a *UGON* 1-p.e. signal. The threshold of  $D_2$  is remotely adjustable in the range  $0.1 - 10 A_1$ , with  $A_1$  corresponding to 1 photoelectron emitted from the *QUASAR-370* photocathode. The output signal from  $D_1$  has to be confirmed by a signal from  $D_2$  (coincidence in Fig. 9). The output pulses from  $D_1$  have 15 nsec length and are switched in coincidence in a way, that the leading edge of the output signal ("*local trigger*") is determined by the first of the two input signals. In this way, late pulses are suppressed.

The dynode signals of a pair of OMs are led to the *Q-T* module and summed by an analog summator. Each summator input can be inhibited remotely (i.e. each OM can be excluded individually from the sum). The sum signal is processed by a charge-to-time converter based on the *Q-T* circuit 1101PD1 (russian analogue to MQT-200 from LeCroy). A local trigger would strobe the 1101PD1, and the input charge is converted, with a maximum conversion time of  $70 \mu\text{sec}$ . The width of the resulting signal corresponds to the charge of the dynode signal, the leading edge is set by the leading edge of the local trigger and defines the timing. The signal is sent to a string electronics module one level higher in the hierarchy and fed into TDCs which digitize the time (11 bit) and the time-converted amplitude information (10 bit) [1].

The *Q-T* module can be operated in two modes. The first uses a time conversion factor just as high that a 1-p.e. signal corresponds to 1 channel of the

amplitude digitizing TDC. In the second ("calibration") mode, the conversion time is stretched and one photoelectron corresponds to 20 TDC bins.

Fig. 14. Scheme of the svjaska electronics controlling 2 pairs of OMs (only the 2 PMTs belonging to the first pair are shown).

## 5.2 Single OM versus OM Pair

In the course of the development the projects DUMAND and BAIKAL, there have been long discussions about the advantages and drawbacks of operating the PMTs as single detectors or as pairs. We have been favouring the pair principle due to the following reasons:

Firstly, the average counting rate per PMT is *in situ*  $(0.5-1) \cdot 10^5$  Hz and, due to bioluminescence, seasonally reaches  $(2-3) \cdot 10^5$  Hz. The coincidence reduces the rate to 100-300 Hz per pair typically. This low counting rate is of significant advantage for the following goals:

a) *data transmission and trigger formation*

The hard local coincidence allows to transmit all local signals to the underwater array trigger module just above the detector, to form an overall trigger, to read out all signals and to transmit digitized times and amplitudes via wire cables to shore. Due to the low rate, a simple underwater hardware trigger (like e.g. " $\geq 3$  local triggers in the whole array within 500 nsec") already gives a sample nearly free of accidental coincidences.

b) *track reconstruction*

In experiments operating the PMTs in single mode, background hits due to PMT noise, bioluminescence or  $K^{40}$  are mixed into practically every event [15]. These hits have to be eliminated by various criteria and repeated fitting procedures rejecting those PMTs with the highest time residuals. For the NT-200 detector, the average number of hits *not* due to the muon track is only 0.03/event, compared to about 10/event for an Ocean experiment operating  $\approx 200$  PMTs in single mode [15]. No coincidence between distant PMTs reaches the noise hit rejection capabilities of the local coincidence, due to the small coincidence window of the latter.

c) *Search for slowly moving bright objects like magnetic GUT monopoles*

The detection principle is the registration of an excess in counting rates over time windows of the order of  $10^2 \mu\text{sec}$ . The rate excesses are buried in the noise signals if the PMT is operated in single mode. Furthermore, non-poissonian fluctuations of a single PMT might fake a monopole event. Noise rates as well as non-poissonian effects are effectively suppressed by the coincidence (see Fig. 15).

Secondly, "late pulses" are strongly suppressed. These are pulses delayed by 10-100 nsec due to (undetected) elastical backscattering of the photoelectrons and multiplication after their second incidence on the dynode system. Since it is rather unlikely that both PMTs give a late pulse and since the response time is derived from the first PMT yielding a signal, only for a very small fraction of events the response time is that of a late pulse.

The time resolution is on the one hand worsened since the azimuthal position of the PMT is unknown ( $\Delta x, \Delta y = \pm 30$  cm, i.e. 1.5 nsec light travel time in water), on the other hand, taking the time flag from the *first* hit PMT of a pair (convolution of eq. (4)) sharpens the time resolution. The two effects almost balance each other.

At least for the NT-200 project (given the high external noise due to bioluminescence and the robust "low-tech" philosophy of the electronics and data

transmission), these advantages prevail the drawbacks which are:

- a) A higher number of PMTs in order to instrument the same volume,
- b) a slightly higher threshold ( $\geq 0.3$  p.e. in *each* of the two PMTs compared to  $\geq 0.3$  p.e. in one PMT),
- c) some mutual shadowing of the two OM's of a pair.
- d) possible signals in one PMT induced by the other PMT.

Fig. 15. Hit multiplicity distributions in a time window of 8 msec, as recorded with the monopole trigger system for two of the 18 channels of *NT-36*. Experimental data are indicated by points, the curve gives the Poisson prediction.

## 6 Calibration

### 6.1 In-situ tests

In 1988/89, in-situ calibrations of cylindrical modules containing a *QUASAR-300* (the early 30-cm variant of the *QUASAR*) and a Philips *XP-2600* have been performed in Lake Baikal. We used a trigger telescope consisting of two tanks clamped to a string at a vertical distance of 6.5 m. The water volume in the tanks was optically shielded from the surrounding water, therefore

the two flat-cathode PMTs watching the tank interior were triggered only by Cherenkov light from muons crossing the tank.

A second string carried a pair of cylindrical OM's with the test tubes. The horizontal distance of this string with respect to the string with the trigger telescope was varied between 5 and 15 meters. Fig. 16 sketches the experimental arrangement and gives the registration probability by the test tubes as a function of the distance between muon and tubes. The curves are the results of MC calculations based on the independently measured values for water transparency, lensing effect and transparency of the plexiglas cap used at that time, and the photocathode sensitivity.

Fig. 16. Determination of the registration probability of vertical muons as a function of their passing distance to the OM. *QUASAR-300* and *QUASAR-350* are the early versions of the *QUASAR* tube, with 30 and 35 cm diameter, respectively.

## 6.2 Plane wave response

A distant muon track illuminates an OM with a nearly plane wave of photons. Given an incident flux of photons,  $\Phi$  [photons/m<sup>2</sup>], the average number of photoelectrons is given by

$$N_{PE} = \Phi \cdot F \cdot S(\theta). \quad (4)$$

Here,  $\theta$  is the zenith angle with respect to the symmetry axis of the OM,  $S(\theta)$  the angular response normalized to unity at  $\theta=0$ , and  $F$  the absolute sensitivity at  $\theta=0$ .  $S(\theta)$  and  $F$  include the relevant information needed for MC calculations.

We have measured the response of OMs to a plane wave from a pulsed LED and have determined  $S(\theta)$  by rotating the OM in the light beam. The experimental setup to measure the angular dependence of the amplitude is shown in Fig. 17. The OM is mounted in a black box filled with water. It can be rotated an axis perpendicular to the light front. The OM is illuminated with a green LED through a plexiglass window. The LED is at a distance of 2.5 meters, the maximum deviation from planarity at the edge of the module is  $4.3^\circ$  for the box filled with water. The measured non-uniformity of the light profile is less than 3% over the module cross section.

Fig. 17. Plane wave test stand

The results are shown in Fig. 18. Data points are normalized to the signal at  $\cos\theta = 0$ . The deviation of the curves from linearity is marginally. Neglecting the region at  $\cos\theta \geq 0.9$ , a linear fit

$$S(\theta) = A + B \cdot \cos\theta \quad (5)$$

yields for the Baikal OMs  $A = 0.49$ ,  $B = 0.51$ , similar to the DUMAND Japanese OMs [12], the DUMAND European OMs measured with the same setup [13], and the AMANDA OMs. Also shown in Fig. 18 is the result of an analytical simulation including all effects of absorption, refraction and reflection [16].

Fig. 18. Angular sensitivity of the Baikal OM (labeled "Quasar") and the Dumand European OM (labeled "XP-2600").

### 6.3 Amplitude and time calibration for the full telescope

The data taking of the telescope is interrupted about twice every week for calibration runs in order to determine the scale parameters of the amplitude and the time information.

#### a) Amplitude

The amplitude scale is calibrated by multi-photoelectron signals from the LED. The average number of photoelectrons  $N_{pe}$  of a charge distribution is derived from

$$N_{pe} = A^2/D^2 \cdot (1 + d)^2 \quad (6)$$

with  $A$  and  $D$  being mean value and dispersion of the distribution, respectively, and  $d$  the relative dispersion of a single-photoelectron signal.  $N_{pe}/A$  gives the scale factor. The high voltage for the *UGON* is changed until one photoelectron corresponds to one amplitude channel.

The second (stretched) *Q-T* mode allows to plot the 1-p.e. spectrum. This allows an independent determination of the 1 p.e. scale factor and measures also the threshold value.

b) Time

The response time  $t_i$  of an OM-pair  $i$  with respect to an arbitrarily chosen time  $t_0$  is determined by two calibration parameters,

$$t_i = \beta_i \cdot n_i + \delta t_i \quad (7)$$

with  $\beta_i$  being the scale factor for the time digitization,  $\delta t_i$  (in nsec) being the relative shifts of channel  $i$  with respect to mean value of all channels, and  $n_i$  the measured TDC-channel number for channel  $i$ .

In the calibration runs, the TDCs are started by noise pulses of the PMTs and stopped by generator pulses with a period  $\tau$ . From a distribution like the one shown in Fig. 19, start and end point of the plateau,  $K_{min}$  and  $K_{max}$ , are determined with an accuracy of 1-2 channels (1-2 nsec for a 10 bit TDC and  $\tau = 1\mu\text{sec}$ ). The  $\beta_i$  are given by  $\tau/(K_{max} - K_{min})_i$ , the flatness of the plateau determines the differential linearity of the TDC, which is better than 1 nsec in our case.

Fig. 19. Determination of the scale factors  $\beta_i$  for time digitization (see text).

The time shifts  $\delta_i$  are determined with a help of a calibration laser. This nitrogen laser, and a dye laser shifting the original wavelength of 337 nm to a spectrum peaking at 475 nm, are housed in a glas cylinder just above the telescope. The light pulses of less than 1 nsec width are guided via optical fibers of equal length to the OM, with one fiber illuminating one OM pair. A laser pulse generated a "laser" event with typically most of the channels

firing. The time shifts  $\delta_i$  are given by [17]:

$$\delta_i = \frac{1}{n_{ch}} \cdot \sum_{j=1}^{n_{ch}} \frac{1}{n_{ji}} \cdot \sum_{l=1}^{n_{ij}} (\beta_i t_{il} - \beta_j t_{jl}) \quad (8)$$

with the first sum running over the total number of channels,  $n_{ch}$ , and the second sum over all events  $n_{ij}$  with both channels  $i$  and  $j$  being fired.  $\beta_i$ ,  $\beta_k$  are the scale factors for channels  $i$  and  $j$ , and  $t_{il}$  and  $t_{jl}$  are the time codes of channel  $i$  and  $j$  within event  $l$ .

Fig. 20 shows the time difference distribution *after* the correction procedure for the second and the sixth channel of the first string of the *NT-36* array. The FWHM of the laser peak is 2 nsec and the peak position is determined with an accuracy better than one nsec. The right peak is due to downward going muons which had also triggered the two channels separated by 25 m ( $\approx 83$  nsec  $\cdot 0.3$  m/nsec).

Fig. 20. Distribution of light arrival time differences  $\Delta t_{i,j} = t_j - t_i$  for channels 2 and 6 (string 1) for a typical laser run, with muon triggers recorded in parallel.

We observed a drift in the  $\delta$  values over several months, presumably due to changes in the speed of light in the fiber under long-time pressure or water diffusion. These small effects can be corrected *a posteriori* by reconstructing

muon tracks and requesting an average time residual like that observed in MC calculations. The overall accuracy of the time calibration is about 2 nsec.

## 7 Long Term Operation Underwater

### 7.1 Reliability

The first year of *NT-36* has demonstrated the stability and reliability of all mechanical elements of the OMs. None of the OMs did leak, none of the polyurethane sealing layers and none of the QUASAR tubes have been damaged. Until 1996, nearly thousand penetrator/valve holes have been drilled in more than 130 spheres (OMs and electrical modules) which afterwards have been operated over one to four years at 1.1 km depth. None of the feedthroughs did leak. Only 2 spheres – in 1995 – leaked slightly due to cracks which had developed after a year underwater. This effect was clearly due to a manufacturing error eliminated in the mean time.

An unexpected problem was discovered with the power lines submitting 300 V to the electronics modules. In 4 out of 30 connectors a parasitic current between the central wire and earth appeared, leading to strong electrolytic currents across the water to the string and particularly to the failure of the 1993 acoustic coordinate monitoring system driven via one of these connectors. The reason for this effect seems to be that, under the pressure of water, the plastificator from the PVC jacket is squeezed into the connector. This does not influence the functionality of the HF lines, but obviously leads to the formation conducting channels in the 300 V connectors. In the mean time, the jackets of the cables have been improved and the effect has disappeared.

Another problem was the initially unacceptably high failure rate of some electronic components. The percentage of working channels, averaged over the full year, was only  $S \approx 70\%$  in 1993/94 (*NT-36*). (An array with a linearly decreasing number of living OMs, starting with 100 % and ending after a year with 50 % living OMs, would have  $S = 75\%$ .) Losses were dominantly due to failures or misoperation of the HV supplies, secondly to failures of the *SEM* controllers. With  $S$  still only 75 % in 1994/95, the year 1995 was used for a total re-design of the 25 kV supply. This, and changes at the 2 kV supply as well as at the controllers led to  $S = 85\%$  for the 1996 array *NT-96*. The goal for the next years will be to increase  $S$  up to 90-95 %. For the OMs alone this number is already nearly reached, and next improvements have to concentrate to other components of the detector.

In summary, the reliability optical module is suitable for long-term underwater

operation in a 200 OM array, taking into account that yearly repair of failed components is possible. For arrays larger by an order of magnitude, further significant improvements are desirable.

## 7.2 Sedimentation

A phenomenon strongly influencing the sensitivity and, consequently, the counting rates of upward facing modules, is sedimentation of biomatter and dust on the upper hemispheres of the modules.

Fig. 21 shows the trigger rates for two different conditions over a period of 225 days, starting with April 13th, 1993. Firstly, for the case that at least 4 upward facing channels have been hit (upper graph), secondly, for the condition that at least 4 downward facing channels have been hit (lower graph). Only channels operating all 225 days have been included. In the second case, one observes a slight decrease of the rates down to 85-90% of its original value. In contrast, the rate for the *upward* trigger falls down by nearly an order of magnitude.

Fig. 21. Trigger rates over a period of 225 days starting with April 13th, 1993. Top: Trigger *4-up* (at least 4 upward channels hit). Bottom: Trigger *4-down* (at least 4 downward channels hit).

The inspection of the spheres after one year of operation showed that sediments had formed a "hat" of bad transmission on the upward facing hemispheres

(see Fig. 22). The region near the equator was almost free of sediments. This suggests to describe the variation of the sensitivity  $\eta$  of an optical module by the following formula:

$$\eta = \eta_0 \cdot (p_1 + (1 - p_1) \cdot e^{-t/p_2}) \quad (9)$$

where  $t$  is the time after deployment in days.  $p_1$  stands for the part of the sensitivity contributed by the equatorial region, the second term describes the top region with exponentially decreasing light transmission.

Replacing the sensitivity  $\eta_0$  used in the Monte-Carlo calculations by  $\eta$  as defined above, and fitting the resulting trigger rates to those experimentally measured in 1993 (1994), one gets  $p_1 = 0.33$  (0.36) and  $p_2 = 96.2$  (102.0) days (numbers in brackets are for the 1994 array *NT-36'*). Consequently, the sensitivity of an upward facing module to atmospheric muons decreases to 35 % after a year. Both parameters change only slightly from year to year. Note that the sensitivity of an upward facing OM to upward going muons from neutrino interactions is influenced less, since in average for these tracks the equatorial part of the module is illuminated stronger than the top region. Presently, we are looking for methods to reduce sedimentation effects. E.g., the accumulation of sediments can be reduced by a smoother OM surface or by dressing the OM with a plexiglas cone (see Fig. 22).

Fig. 22. Sedimentation on upward facing modules (region  $p_1$  – negligible sedimentation, region  $p_2$  – exponentially decreasing sensitivity due to sedimentation(see eq. 9). The dashed lines indicate the plexiglas cone to prevent sedimentation on the sphere.

The straight-forward solution is of course to direct all OM's downward. This increases the sensitivity to upward muons from neutrino interactions by 20-30 %, slightly reduces the identification capabilities with respect to fake event (downward muons faking upward muons), and limits the precision of downward muon physics. In the presently operating array *NT-200*, 160 of the 192 OM's face downward.

### 7.3 Track Reconstruction

During 4 years of data taking with the stepwise increasing stages of the Baikal Neutrino Telescope we have accumulated technical and methodical experience as well as first relevant results. Physics results from *NT-36* are reported in [1], and from *NT-96* in [18,19].

Fig. 23. Single muon event recorded with *NT-36*. Hit channels are in black. The thick line gives the reconstructed path, thin lines pointing to the channels mark the path of Cherenkov photons as given by the fit to the measured times. The sizes of the ellipses are proportional to the recorded amplitudes.

Fig. 24. A neutrino event with 19 hits, recorded with *NT-96*. The fake probability of this event is smaller than 1 %.

The initial test an underwater telescope has to undergo is the correct reconstruction of atmospheric muons. They enter the array from above and are recorded with a frequency of several Hz. Fig. 24 shows a typical single muon event firing 7 of the 18 channels of *NT-36* and reconstructed with a  $\chi^2/NDF = 0.57$ . Monte Carlo calculations using as input the timing and am-

plitude properties of the *QUASAR* measured in laboratory do well reproduce the experimental data like amplitudes, time differences and angular distribution [1].

The crucial demonstration of the functionality of a neutrino telescope is the identification of the rare neutrino events among the huge amount of atmospheric muons. Their signature is given by a muon entering the array from *below*. Still too small to detect the feeble fluxes from extraterrestrial neutrino sources, *NT-200* will be used to investigate those neutrinos which have been generated in the atmosphere in interactions of charged cosmic rays ("atmospheric neutrinos") and to search for neutrinos due to dark matter annihilation in the center of the Earth [19]. In *NT-200*, about one neutrino per day will be recorded. With *NT-36* and *NT-96*, 14 neutrino events have been identified, in accordance with Monte Carlo estimates. Fig. 25 shows one "gold plated" event with 19 hits.

## 8 Summary and Outlook

We have constructed a deep underwater Optical Module (OM) which is the key component of the neutrino telescope in Lake Baikal. Most parts of the OM, like the phototube *QUASAR-370*, the pressure sphere protecting the *QUASAR*, electronics as well as connectors and feedthroughs have been developed by our collaboration, in close cooperation with industry.

Since 1993, we have been permanently operating configurations with a growing number of OMs. A number of scientifically relevant results have been obtained, ranging from counting rate variations which reflect water transport processes to a precise measurement of the angular spectrum of atmospheric muons. Most notably, first neutrino events have been unambiguously identified. During all years of data taking, none of the pressure housing did leak, and the reliability of the OMs has been improved continuously.

The 144-OM array operated in 1997 was upgraded to 192 OMs in April 1998. With this upgrade (*NT-200*), the short term goal of the collaboration is completed.

The technical solutions used until now turned out to be adequate for a first generation neutrino telescope like *NT-200*. In the next step, we envisage a telescope consisting of 1000-2000 OMs. For this telescope, the OM design will change in various respects. Firstly, an array much larger than *NT-200* calls for higher reliability. Some basic peculiarities of the Baikal telescope may change. The present electronics was conceptually developed in 1988-1990. Clearly, a new design of the electronics is necessary, using higher integrated circuitry,

eventually omitting the "svjaska electronics modules" and moving the corresponding functions to the OM or to the string electronics modules, making use of more advanced signal transmission techniques etc. Almost for sure, a future OM will have less feed-throughs in order to further minimize the danger of leaks. This, in turn, request changes in the electronics. For instance, one might be forced to omit the separate dynode read-out for amplitude measurement and pay for that with a somewhat smaller dynamic range.

As an example for future developments of the OM we focus here on its main component, the *QUASAR*-tube.

Amplitude and timing characteristics of the *QUASAR-370* depend strongly on the ratio  $\frac{G}{\tau}$  (eq. 3). We are investigating some new scintillator materials like  $\text{ScBO}_3\text{:Ce}$  (SBO),  $\text{YAlO}_3\text{:Ce}$  (YAO) and  $\text{YClO}_5\text{:Ce}$  (YCO), with 2-3 times larger light yield than  $\text{Y}_2\text{SiO}_5\text{:Ce}$  (YSO) and 28-30 ns decay time. We have manufactured each 5 pilot tubes with SBO and YAO. The average gain values of the corresponding preamplifier tubes turned out to be twice as high as for fo YSO,  $G = 50-60$ . The single photoelectron resolution is less than 50 % and the time resolution about 1 nsec.

Technological improvements like the chemical protection of single scintillator grains are expected to give a larger gain  $G$  in tubes with ordinary  $\text{Y}_2\text{SiO}_5\text{:Ce}$ . Other lines of improvement are directed to increase significantly the photocathode sensitivity and to decrease the dark current rate. For the present version, the average dark current rate is about 35 kHz at room temperature and half of that at 0°C.

Another line of principal re-design and improvement is the replacement of the scintillator screen and the small PMT by an diode array or by a foil first dynode followed by a mesh dynode chain. All these improvement make the *QUASAR* increasingly interesting to other fields apart from underwater telescopes, in particular for Air-Cherenkov Telescopes.

As mentioned in section 5.2, we preferred a pairwise operation of OMs by different reasons, most notably effective suppression of noise counts and elimination of prepulses, late pulse and afterpulses. However, for much larger projects the high cost of this approach may be not acceptable. In order to maintain the local coincidence and, at the same time, to reduce the number of OMs, we have developed a two-channel version of the *QUASAR*. We made use of the fact, that photoelectrons of the central part of the *QUASAR* are focussed onto the central spot of the luminescent screen, whereas photoelectrons from peripheral regions are collected onto the circular edge area of the screen. We have developed 2 pilot samples of a two-channel, small (3cm diameter) version of the UGON with a mesh dynode system, one channel collecting photoelectrons from the central region, the other from the periphery. The cross-talks

measured are about 2 %. Switching the two channels in coincidence results in a noise rate as low as 100 Hz.
